A lot of people are awesome, especially you, since you probably agreed to read
this when it was a draft.

Chapter 0

Total $\text{Ha}(\pi^-, \text{Ar})$ dronic Cross

Section Measurement Methodology

This chapter describes the general procedure employed to measure a total hadronic differential cross section in LArIAT. Albeit with small differences, both the (π^-, Ar) and (K^+, Ar) total hadronic cross section measurements rely on the same procedure described in details in the following sections. We start by selecting the particle of interest using a combination of beamline detectors and TPC information (Section 0.1). We then perform a handshake between the beamline information and the TPC tracking to assure the selection of the right TPC track (Section 0.2). Finally, we apply the “thin slice” method and measure the “raw” hadronic cross section (Section 0.3). A series of corrections are then evaluated to obtain the “true” cross section (Section 0.3.3).

At the end of this chapter, we show a sanity check of the methodology against MC truth information (Section 0.4).

0.1 Event Selection

The measurement of the (π^-, Ar) and (K^+, Ar) total hadronic cross section in LArIAT starts by selecting the pool of pion or kaon candidates and measuring their momentum. This is done through the series of selections on beamline and TPC information described in the next sections. The summary of the event selection in data is reported in Table 1.

Selection of Beamline Events

As shown in equation 5, we leverage the beamline particle identification and momentum measurement before entering the TPC as in input to evaluate the kinetic energy for the hadrons used in the cross sections measurements. Thus, we select the LArIAT data to keep only events whose wire chamber and time of flight information is registered (line 2 in in Table 1). Additionally, we perform a check of the plausibility of the trajectory inside the beamline detectors: given the position of the hits in the four wire chambers, we make sure the particle's trajectory does not cross any impenetrable material such as the collimator and the magnets steel (line 3 in in Table 1).

| | Run-II Negative Polarity | Run-II Positive Polarity |

Table 1: Number of data events for Run-II Negative and Positive polarity

89 Particle Identification in the beamline

90 In data, the main tool to establish the identity of the hadron of interest is the LArIAT
 91 tertiary beamline, in its function of mass spectrometer. We combine the measurement
 92 of the time of flight, TOF , and the beamline momentum, p_{Beam} , to reconstruct the
 93 invariant mass of the particles in the beamline, m_{Beam} , as follows

$$m_{Beam} = \frac{p_{Beam}}{c} \sqrt{\left(\frac{TOF * c}{l}\right)^2 - 1}, \quad (1)$$

94 where c is the speed of light and l is the length of the particle's trajectory between
 95 the time of flight paddels.

96 Figure 1 shows the mass distribution for the Run II negative polarity runs on the
 97 left and positive polarity runs on the right. We perform the classification of events
 98 into the different samples as follows:

- 99 • $\pi/\mu/e$: mass < 350 MeV
- 100 • kaon: 350 MeV < mass < 650 MeV
- 101 • proton: 650 MeV < mass < 3000 MeV.

102 Lines 4 and 5 in in Table 1 show the number of negative $\pi/\mu/e$ and positive K
 103 candidates which pass the mass selection for LArIAT Run-II data.

104 TPC Selection: Halo mitigation

105 The secondary beam impinging on LArIAT secondary target produces a plethora of
 106 particles which propagates downstream. The presence of upstream and downstream
 107 collimators greatly abates the number of particles tracing down the LArIAT tertiary
 108 beamline. However, it is possible that more than one particle sneaks into the LArTPC
 109 during its readout time: the TPC readout is triggered by the particle firing the

Figure 1: Distribution of the beamline mass as calculated according to equation 1 for the Run-II events reconstructed in the beamline, negative polarity runs on the left and positive polarity runs on the right. The classification of the events into $\pi^\pm/\mu^\pm/e^\pm$, K^\pm , or (anti)proton is based on these distributions, whose selection cut are represented by the vertical colored lines.

beamline detectors, but particles from the beam halo might be present in the TPC at the same time. We call “pile up” the additional traces in the TPC. We adjusted the primary beam intensity between LArIAT Run I and Run II to reduce the presence of events with high pile up particles in the data sample. For the cross section analyses, we remove events with more than 4 tracks in the first 14 cm upstream portion of the TPC from the sample (line 6 in in Table 1).

TPC Selection: Shower Removal

In the case of the (π^-, Ar) cross section, the resolution of beamline mass spectrometer is not sufficient to select a beam of pure pions. In fact, muons and electrons survive the selection on the beamline mass. It is important to notice that the composition of the negative polarity beam is mostly pions, as will be discussed in section 1.1.1. Anyhow, we devise a selection on the TPC information to mitigate the presence of

Figure 2: Visual rendering of the shower filter. The ROI is a cut cone, with a small radius of 4 cm, a big radius of 10 cm and an height of 42 cm (corresponding to 3 radiation lengths for electrons in Argon).

122 electrons in the sample used for the pion cross section. The selection relies on the
 123 different topologies of a pion and an electron event in the argon: while the former
 124 will trace a track inside the TPC active volume, the latter will tend to “shower”, i.e.
 125 interact with the medium, producing bremsstrahlung photons which pair convert into
 126 several short tracks. In order to remove the shower topology, we create a region of
 127 interest (ROI) around the TPC track corresponding to the beamline particle (more
 128 details on this in the next section). We look for short tracks contained in the ROI,
 129 as depicted in figure 4: if more then 5 tracks shorter than 10 cm are in the ROI,
 130 we reject the event. Line 8 in in Table 1) shows the number of events surviving this
 131 selection.

132 0.2 Beamline and TPC Handshake: the Wire Cham- 133 ber to TPC Match

134 For each event passing the selection on its beamline information, we need to identify
 135 the track inside the TPC corresponding to the particle which triggered the beamline
 136 detectors, a procedure we refer to as “WC to TPC match” (WC2TPC for short).
 137 In general, the TPC tracking algorithm will reconstruct more than one track in the
 138 event, partially due to the fact that hadrons interact in the chamber and partially

Figure 3: Kaon candidate event: on the right, event display showing raw quantities; on the left, event display showing reconstructed tracks. In the reconstructed event display, different colors represent different track objects. A kink is visible in the kaon ionization, signature of a hadronic interaction: the tracking correctly stops at the kink position and two tracks are formed. An additional pile-up track is so present in the event (top track).

139 because of pile up particles during the triggered TPC readout time, as shown in
 140 figure 3.

141 We attempt to uniquely match one wire chamber track to one and only one re-
 142 constructed TPC track. In order to determine if the presence of a match, we apply
 143 a geometrical selection on the relative the position of the wire chamber and TPC
 144 tracks. We start by considering only TPC tracks whose first point is in the first 2
 145 cm upstream portion of the TPC for the match. We project the wire chamber track
 146 to the TPC front face where we define the coordinates of the projected point as x_{FF}
 147 and y_{FF} . For each considered TPC track, we define ΔX as the difference between
 148 the x position of the most upstream point of the TPC track and x_{FF} . ΔY is defined
 149 analogously. We define the radius difference, ΔR , as $\Delta R = \sqrt{\Delta X^2 + \Delta Y^2}$. We de-
 150 fine as α the angle between the incident WC track and the TPC track in the plane
 151 that contains them. If $\Delta R < 4$ cm, $\alpha < 8^\circ$, a match between WC-track and TPC
 152 reconstructed track is found. We describe how we determine the value for the radius
 153 and angular selection in sec 1.2.1. In MC, we mimic the matching between the WC
 154 and the TPC track by constructing a fake WC track using truth information at wire
 155 chamber four. We then apply the same WC to TPC matching algorithm as in data.
 156 We discard events with multiple WC2TPC matches. We use only those TPC tracks
 157 that are matched to WC tracks in the cross section calculation.

Figure 4: Visual rendering of the wire chamber to TPC match.

0.3 The Thin Slice Method

Once we have selected the pool of hadron candidates and we have identified the TPC track corresponding to the beamline event, we apply the thin slice method to measure the cross section, as the following sections describe.

0.3.1 Cross Sections on Thin Target

Cross section measurements on a thin target have been the bread and butter of nuclear and particle experimentalists since the Geiger-Marsden experiments [?]. At their core, these types of experiments consist in shooting a beam of particles with a known flux on a thin target and recording the outgoing flux.

In general, the target is not a single particle, but rather a slab of material containing many diffusion centers. The so-called “thin target” approximation assumes that the target centers are uniformly distributed in the material and that the target is thin compared to the projectile interaction length, $WC2TPC$ so that no center of interaction sits in front of another. In this approximation, the ratio between the number of particles interacting in the target $N_{Interacting}$ and number of incident particles $N_{Incident}$ determines the interaction probability $P_{Interacting}$, which is the complementary to one of the survival probability $P_{Survival}$. Equation 2

$$P_{Survival} = 1 - P_{Interacting} = 1 - \frac{N_{Interacting}}{N_{Incident}} = e^{-\sigma_{TOT}n\delta X} \quad (2)$$

describes the probability for a particle to survive the thin target. This formula relates the total cross section σ_{TOT} , the density of the target centers n and the thickness of the target along the incident hadron direction δX , to the interaction probability¹. If the target is thin compared to the interaction length of the process considered, we can Taylor expand the exponential function in equation 2 and find a simple proportionality relationship between the number of incident and interacting particles, and the cross section, as shown in equation 3:

$$1 - \frac{N_{Interacting}}{N_{Incident}} = 1 - \sigma_{TOT} n \delta X + O(\delta X^2). \quad (3)$$

Solving for the cross section, we find:

$$\sigma_{TOT} = \frac{1}{n \delta X} \frac{N_{Interacting}}{N_{Incident}}. \quad (4)$$

0.3.2 Not-so-Thin Target: Slicing the Argon

The interaction length of pions and kaons in argon is expected to be of the order of 50 cm for pions and 100 cm for kaons. Thus, the LArIAT TPC, with its 90 cm of length, is not a thin target. However, the fine-grained tracking of the LArIAT LArTPC allows us to treat the argon volume as a sequence of many adjacent thin targets.

As described in Chapter ??, LArIAT wire planes consist of 240 wires each. The wires are oriented at +/- 60° from the vertical direction at 4 mm spacing, while the beam direction is oriented 3 degrees off the z axis in the XZ plane. The wires collect signals proportional to the energy loss of the hadron along its path in a $\delta X = 4 \text{ mm} / \sin(60^\circ) \approx 4.7 \text{ mm}$ slab of liquid argon. Thus, one can think to slice the TPC

1. The scattering center density in the target, n , relates to the argon density ρ , the Avogadro number N_A and the argon molar mass m_A as $n = \frac{\rho N_A}{m_A}$.

194 into many thin targets of $\delta X = 4.7$ mm thickness along the direction of the incident
 195 particle, making a measurement at each wire along the path.

196 Considering each slice j a “thin target”, we can apply the cross section calculation
 197 from Eq. 4 iteratively, evaluating the kinetic energy of the hadron as it enters each
 198 slice, E_j^{kin} . For each WC2TPC matched particle, the energy of the hadron entering
 199 the TPC is known thanks to the momentum and mass determination by the tertiary
 200 beamline,

$$E_{FrontFace}^{kin} = \sqrt{p_{Beam}^2 - m_{Beam}^2} - m_{Beam} - E_{loss}, \quad (5)$$

201 where E_{loss} is a correction for the energy loss in the dead material between the
 202 beamline and the TPC front face. The energy of the hadron at each slab is determined
 203 by subtracting the energy released by the particle in the previous slabs. For example,
 204 at the j^{th} point of a track, the kinetic energy will be

$$E_j^{kin} = E_{FrontFace}^{kin} - \sum_{i < j} \Delta E_i, \quad (6)$$

205 where ΔE_i is the energy deposited at each argon slice before the j^{th} point as measured
 206 by the calorimetry associated with the tracking.

207 If the particle enters a slice, it contributes to $N_{Incident}(E^{kin})$ in the energy bin
 208 corresponding to its kinetic energy in that slice. If it interacts in the slice, it then
 209 also contributes to $N_{Interacting}(E^{kin})$ in the appropriate energy bin. The cross section
 210 as a function of kinetic energy, $\sigma_{TOT}(E^{kin})$ will then be proportional to the ratio
 211 $\frac{N_{Interacting}(E^{kin})}{N_{Incident}(E^{kin})}$.

212 The statistical uncertainty for each energy bin is calculated by error propagation
 213 from the statistical uncertainty on $N_{Incident}$ and $N_{Interacting}$. Since the number of
 214 incident hadrons in each energy bin is given by a simple counting, we assume that
 215 $N_{Incident}$ is distributed as a poissonian with mean and σ^2 equal to $N_{Incident}$ in each

bin. On the other hand, $N_{Interacting}$ follows a binomial distribution: a particle in a given energy bin might or might not interact. The square of the variance for the binomial is given by

$$\sigma^2 = \mathcal{N} P_{Interacting} (1 - P_{Interacting}); \quad (7)$$

since the interaction probability $P_{Interacting}$ is $\frac{N_{Interacting}}{N_{Incident}}$ and the number of tries \mathcal{N} is $N_{Incident}$, equation 7 translates into

$$\sigma^2 = N_{Incident} \frac{N_{Interacting}}{N_{Incident}} \left(1 - \frac{N_{Interacting}}{N_{Incident}}\right) = N_{Interacting} \left(1 - \frac{N_{Interacting}}{N_{Incident}}\right). \quad (8)$$

$N_{Incident}$ and $N_{Interacting}$ are not independent. The uncertainty on the cross section is thus calculated as

$$\delta\sigma_{tot}(E) = \sigma_{tot}(E) \left(\frac{\delta N_{Interacting}}{N_{Interacting}} + \frac{\delta N_{Incident}}{N_{Incident}} \right) \quad (9)$$

where:

$$\delta N_{Incident} = \sqrt{N_{Incident}} \quad (10)$$

$$\delta N_{Interacting} = \sqrt{N_{Interacting} \left(1 - \frac{N_{Interacting}}{N_{Incident}}\right)}. \quad (11)$$

0.3.3 Corrections to the Raw Cross Section

Equation 4 is a prescription for measuring the cross section in case of a pure beam of the hadron of interest and 100% efficiency in the determination of the interaction point. For example, if LArIAT had a beam of pure pions and were 100% efficient in determining the interaction point within the TPC, the pion cross section in each energy bin would be given by

$$\sigma^{\pi^-}(E_i) = \frac{1}{n\delta X} \frac{N_{Interacting}^{\pi^-}(E_i)}{N_{Incident}^{\pi^-}(E_i)}. \quad (12)$$

Unfortunately, this is not the case. In fact, the selection used to isolate pions in the LArIAT beam allows for the presence of some muons and electrons as background. Also, the LArIAT TPC is not 100% efficient in determining the interaction point. Therefore we need to apply two corrections evaluated on the MC in order to extract the cross section from LArIAT data: the background subtraction and the efficiency correction. Still using the pion case as example, we estimate the pion cross section in each energy bin changing the equation 12 into

$$\sigma^{\pi^-}(E_i) = \frac{1}{n\delta X} \frac{N_{\text{Interacting}}^{\pi^-}(E_i)}{N_{\text{Incident}}^{\pi^-}(E_i)} = \frac{1}{n\delta X} \frac{\epsilon_i^{\text{inc}}[N_{\text{Interacting}}^{\text{TOT}}(E_i) - B_{\text{Interacting}}(E_i)]}{\epsilon_i^{\text{int}}[N_{\text{Incident}}^{\text{TOT}}(E_i) - B_{\text{Incident}}(E_i)]}, \quad (13)$$

where $N_{\text{Interacting}}^{\text{TOT}}(E_i)$ and $N_{\text{Incident}}^{\text{TOT}}(E_i)$ is the measured content of the interacting and incident histograms for events that pass the event selection, $B_{\text{interacting}}(E_i)$ and $B_{\text{Incident}}(E_i)$ represent the contributions from beamline background, and ϵ_i^{int} and ϵ_i^{inc} are the efficiency corrections for said histograms.

As we will show in section ??, the background subtraction for the interacting and incident histograms can be translated into a corresponding corrections $C_{\text{Interacting}}^{\pi MC}(E_i)$ and $C_{\text{Incident}}^{\pi MC}(E_i)$ and the cross section re-written as follows

$$\sigma^{\pi^-}(E_i) = \frac{1}{n\delta X} \frac{\epsilon_i^{\text{inc}} N_{\text{Interacting}}^{\text{TOT}}(E_i) C_{\text{Interacting}}^{\pi MC}(E_i)}{\epsilon_i^{\text{int}} N_{\text{Incident}}^{\text{TOT}}(E_i) C_{\text{Incident}}^{\pi MC}(E_i)}. \quad (14)$$

0.4 Procedure testing with truth quantities

The (π^-, Ar) and (K^+, Ar) total hadronic cross section implemented in Geant4 can be used as a tool to validate the measurement methodology. We describe here a closure test done on Monte Carlo to prove that the methodology of slicing the TPC retrieves the underlying cross section distribution implemented in Geant4 within the statistical uncertainty.

For pions in the considered energy range, **the Geant4 inelastic model adopted to**

251 is “BertiniCascade”, while the elastic model “hElasticLHEP”. For kaons, the Geant4
252 inelastic model adopted to is “BertiniCascade”, while the elastic model “hElasti-
253 cLHEP”.

254 For the validation test, we fire about a sample of pions and a sample of kaons
255 inside the LArIAT TPC active volume using the Data Driven Monte Carlo (see section
256 1.1.2). We apply the thin-sliced method using only true quantities to calculate the
257 hadron kinetic energy at each slab in order to decouple reconstruction effects from
258 issues with the methodology. For each slab of 4.7 mm length along the path of the
259 hadron, we integrate the true energy deposition as given by the Geant4 transportation
260 model. Then, we recursively subtracted it from the hadron kinetic energy at the TPC
261 front face to evaluate the kinetic energy at each slab until the true interaction point is
262 reached. Since the MC is a pure beam of the hadron of interest and truth information
263 is used to retrieve the interaction point, no correction is applied. Doing so, we obtain
264 the true interacting and incident distributions for the considered hadron and we obtain
265 the true MC cross section as a function of the hadron true kinetic energy.

266 Figure 5 shows the total hadronic cross section for argon implemented in Geant4
267 10.01.p3 (solid lines) overlaid with the true MC cross section as obtained with the
268 sliced TPC method (markers) for pions on the left and kaons on the right; the total
269 cross section is shown in green, the elastic cross section in blue and the inelastic
270 cross section in red. The nice agreement with the Geant4 distribution and the cross
271 section obtained with the sliced TPC method gives us confidence in the validity of
272 the methodology.

Figure 5: Hadronic cross sections for (π^-, Ar) on the left and (K^+, Ar) on the right as implemented in Geant4 10.01.p3 (solid lines) overlaid the true MC cross section as obtained with the sliced TPC method (markers). The total cross section is shown in green, the elastic cross section in blue and the inelastic cross section in red.

Chapter 1

Preparatory Work

This chapter describes the preparatory work done on the the data and Monte Carlo samples used for the cross section analyses. This entails:

1. the MC production,
2. the energy calibration of the detector both in data and MC,
3. the optimization of the tracking algorithm for the total cross section analyses.

299 Measurement of LArIAT Electric 300 Field

301 The electric field of a LArTPC in the drift volume is a fundamental quantity for
302 the proper functionality of this technology, as it affects almost every reconstructed
303 quantity such as the position of hits or their collected charge. Given its importance,
304 we calculate the electric field for LArIAT with a single line diagram from our HV
305 circuit and we cross check the obtained value with a measurement relying only on
306 TPC data.

307 Before getting into the details of the measurement procedures, it is important to
308 explicit the relationship between some quantities in play. The electric field and the
309 drift velocity (v_{drift}) are related as follows

$$v_{drift} = \mu(E_{field}, T)E_{field}, \quad (A.1)$$

310 where μ is the electron mobility, which depends on the electric field and on the
311 temperature (T). The empirical formula for this dependency is described in [?] and
312 shown in Figure A.1 for several argon temperatures.

313 The relationship between the drift time (t_{drift}) and the drift velocity is trivially

Figure A.1: Drift velocity dependence on electric field for several temperatures. The slope of the line at any one point represents the electron mobility for that given temperature and electric field.

Table A.1: Electric field and drift velocities in LArIAT smaller drift volumes

| | Shield-Induction | Induction-Collection |
|-------------|------------------|----------------------|
| E_{field} | 700.63 V/cm | 892.5 V/cm |
| v_{drift} | 1.73 mm/ μ s | 1.90 mm/ μ s |
| t_{drift} | 2.31 μ s | 2.11 μ s |

314 given by

$$t_{drift} = \Delta x / v_{drift}, \quad (\text{A.2})$$

315 where Δx is the distance between the edges of the drift region. Table A.1 reports the
316 values of the electric field, drift velocity, and drift times for the smaller drift volumes.

317 With these basic parameters established, we can now move on to calculating the
318 electric field in the main drift region (between the cathode and the shield plane).

Single line diagram method

The electric field strength in the LArIAT main drift volume can be determined knowing the voltage applied to the cathode, the voltage applied at the shield plane, and the distance between them. We assume the distance between the cathode and the shield plane to be 470 mm and any length contraction due to the liquid argon is negligibly small (~ 2 mm).

The voltage applied to the cathode can be calculated using Ohm's law and the single line diagram shown in Figure A.2. A set of two of filter pots for emergency power dissipation are positioned between the Glassman power supply and the cathode, one at each end of the feeder cable, each with an internal resistance of $40\text{ M}\Omega$.

Given the TPC resistor chain, the total TPC impedance is $6\text{ G}\Omega$. Since the total resistance on the circuit is driven by the TPC impedance, we expect the resulting current to be

$$I = V_{PS}/R_{tot} = -23.5\text{ kV}/6\text{ G}\Omega \sim 4\text{ }\mu\text{A}, \quad (\text{A.3})$$

which we measure with the Glassman power supply, shown in Figure A.3.

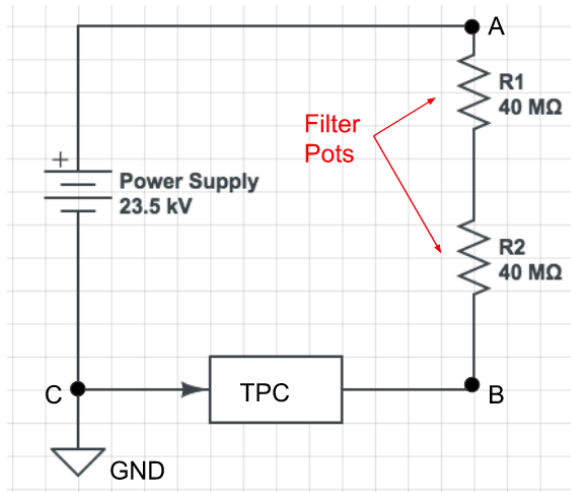

Figure A.2: LArIAT HV simple schematics.

Figure A.3: Current reading from the Glassman between May 25th and May 30th, 2016 (typical Run-II conditions).

333 Using this current, the voltage at the cathode is calculated as

$$V_{BC} = V_{PS} - (I \times R_{eq}) = -23.5 \text{ kV} + (0.00417 \text{ mA} \times 80 \text{ M}\Omega) = -23.17 \text{ kV}, \quad (\text{A.4})$$

334 where I is the current and R_{eq} is the equivalent resistor representing the two filter
335 pots. The electric field is then calculated to be

$$E_{\text{field}} = \frac{V_{BC} - V_{\text{shield}}}{\Delta x} = 486.54 \text{ V/cm}. \quad (\text{A.5})$$

336 **E field using cathode-anode piercing tracks**

337 We devise an independent method to measure the drift time (and consequently drift
338 velocity and electric field) using TPC cathode to anode piercing tracks. We use this
339 method as a cross check to the single line method. The basic idea is simple:

- 340 0. Select cosmic ray events with only 1 reconstructed track
- 341 1. Reduce the events to the one containing tracks that cross both anode and cath-
342 ode
- 343 2. Identify the first and last hit of the track
- 344 3. Measure the time difference between these two hits (Δt).

345 This method works under the assumptions that the time it takes for a cosmic particle
346 to cross the chamber ($\sim \text{ns}$) is small compared to the charge drift time ($\sim \text{hundreds}$
347 of μs).

348 We choose cosmic events to allow for a high number of anode to cathode piercing
349 tracks (ACP tracks), rejecting beam events where the particles travel almost perpen-
350 dicularly to drift direction. We select events with only one reconstructed track to
351 maximize the chance of selecting a single crossing muon (no-michel electron). We
352 utilize ACP tracks because their hits span the full drift length of the TPC, see figure

353 A.4, allowing us to define where the first and last hit of the tracks are located in space
354 regardless of our assumption of the electric field.

355 One of the main features of this method is that it doesn't rely on the measurement
356 of the trigger time. Since Δt is the time difference between the first and last hit of a
357 track and we assume the charge started drifting at the same time for both hits, the
358 measurement of the absolute beginning of drift time t_0 is unnecessary. We boost the
359 presence of ACP tracks in the cosmic sample by imposing the following requirements
360 on tracks:

- 361 • vertical position (Y) of first and last hits within ± 18 cm from TPC center
362 (avoid Top-Bottom tracks)
- 363 • horizontal position (Z) of first and last hits within 2 and 86 cm from TPC front
364 face (avoid through going tracks)
- 365 • track length greater than 48 cm (more likely to be crossing)
- 366 • angle from the drift direction (phi in figure A.5) smaller than 50 deg (more
367 reliable tracking)
- 368 • angle from the beam direction (theta in figure A.5) greater than 50 deg (more
369 reliable tracking)

370 Tracks passing all these selection requirements are used for the Δt calculation.

371 For each track passing our selection, we loop through the associated hits to retrieve
372 the timing information. The analysis is performed separately on hits on the collection
373 plane and induction plane, but lead to consistent results. As an example of the time
374 difference, figures A.6 and A.7 represent the difference in time between the last and
375 first hit of the selected tracks for Run-II Positive Polarity sample on the collection
376 and induction plane respectively. We fit with a Gaussian to the peak of the Δt
377 distributions to extract the mean drift time and the uncertainty associated with it.

378 The long tail at low Δt represents contamination of non-ACP tracks in the track
 379 selection. We apply the same procedure to Run-I and Run-II, positive and negative
 380 polarity alike.

381 To convert Δt recorded for the hits on the induction plane to the drift time we
 382 employ the formula

$$t_{drift} = \Delta t - t_{S-I} \quad (\text{A.6})$$

383 where t_{drift} is the time the charge takes to drift in the main volume between the
 384 cathode and the shield plane and t_{S-I} is the time it takes for the charge to drift from
 385 the shield plane to the induction plane. In Table A.1 we calculated the drift velocity
 386 in the S-I region, thus we can calculate t_{S-I} as

$$t_{S-I} = \frac{l_{S-I}}{v_{S-I}} = \frac{4mm}{1.73mm/\mu s} \quad (\text{A.7})$$

387 where l_{S-I} is the distance between the shield and induction plane and v_{S-I} is the drift
 388 velocity in the same region. A completely analogous procedure is followed for the hits
 389 on the collection plane, taking into account the time the charge spent in drifting from
 390 shield to induction as well as between the induction and collection plane. The value
 391 for Δt_{drift} , the calculated drift velocity (v_{drift}), and corresponding drift electric field
 392 for the various run periods is given in Table A.2 and are consistent with the electric
 393 field value calculated with the single line diagram method.

Delta t_{drift} , drift v and E field with ACP tracks

| Data Period | $\Delta t_{Drift} [\mu s]$ | Drift velocity $[mm/\mu s]$ | E field $[V/cm]$ |
|------------------------------------|----------------------------|-----------------------------|------------------|
| RunI Positive Polarity Induction | 311.1 ± 2.4 | 1.51 ± 0.01 | 486.6 ± 21 |
| RunI Positive Polarity Collection | 310.9 ± 2.6 | 1.51 ± 0.01 | 487.2 ± 21 |
| RunII Positive Polarity Induction | 315.7 ± 2.8 | 1.49 ± 0.01 | 467.9 ± 21 |
| RunII Positive Polarity Collection | 315.7 ± 2.7 | 1.49 ± 0.01 | 467.9 ± 21 |
| RunII Negative Polarity Induction | 315.9 ± 2.6 | 1.49 ± 0.01 | 467.1 ± 21 |
| RunII Negative Polarity Collection | 315.1 ± 2.8 | 1.49 ± 0.01 | 470.3 ± 21 |
| Average Values | 314.1 | 1.50 ± 0.01 | 474.3 ± 21 |

Table A.2: Δt for the different data samples used for the Anode-Cathode Piercing tracks study.

Figure A.4: Pictorial representation of the YX view of the TPC. The distance within the anode planes and between the shield plane and the cathode is purposely out of proportion to illustrate the time difference between hits on collection and induction. An ACP track is shown as an example.

Figure A.5: Angle definition in the context of LArIAT coordinate system.

Figure A.6: Collection plane Δt fit for Run II positive polarity ACP data selected tracks.

Figure A.7: Induction plane Δt fit for Run II positive polarity ACP data selected tracks.
